Motivation:

- ullet With a simple linear regression model we learned a model in which a **single** independent variable x explains (or affect) a dependent variable y.
- ullet If we add more factors to our model that are useful for explaining y, then more of the variation in y can be explained.

We can build better models for predicting the dependent variable.

Example: log(wage)

$$\log(wage) = \beta_0 + \beta_1 e duc + u$$

Efficiency of OLS: The Gauss-Markov ullet In the model with two explanatory variables, the key assumption about how u is related to x_1 and x_2 is:

$$E(u|x_1,x_2)=0.$$

- ullet For any values of x_1 and x_2 in the population, the average unobservable is equal to zero.
- ullet The value zero is not important because we have an intercept, eta_0 in the equation.

- In the wage equation, the assumption is E(u|educ, IQ) = 0.
- \bullet Now u no longer contains intelligence, and so this condition has a better chance of being true.
- ullet Recall that in the simple regression, we had to assume IQ and educ are unrelated to justify leaving IQ in the error term.
- ullet Other factors, such as workforce experience and "motivation," are part of u. Motivation is very difficult to measure. Experience is easier:

$$\log(wage) = \beta_0 + \beta_1 e duc + \beta_2 IQ + \beta_3 exper + u.$$

• Let $lwage = \log(wage)$:

$$lwage = \beta_0 + \beta_1 e duc + \beta_2 IQ + \beta_3 exper + \beta_4 exper^2 + u,$$

so that exper is allowed to have a quadratic effect on lwage.

• Thus, $x_1 = educ$, $x_2 = IQ$, $x_3 = exper$, and $x_4 = exper^2$. Note that x_4 is a a nonlinear function of x_3 .

Least Squares Method

• As in the simple regression case, different ways to motivate OLS. We choose $\hat{\beta}_0$, $\hat{\beta}_1$, and $\hat{\beta}_2$ (so three unknowns) to minimize the sum of squared residuals,

$$\sum_{i=1}^{n} (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_{i1} - \hat{\beta}_2 x_{i2})^2$$

• The case with k independent variables is easy to state: choose the k+1 values $\hat{\beta}_0$, $\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_k$ to minimize

$$\sum_{i=1}^{n} (y_i - \hat{\beta}_0 - \hat{\beta}_1 x_{i1} - \dots - \hat{\beta}_k x_{ik})^2$$

$$y \text{ on } x_1, x_2, ..., x_k$$

or

$$y_i$$
 on $x_{i1}, x_{i2}, ..., x_{ik}, i = 1, ..., n$

when we want to emphasize the sample being used.

Interpretation:

- .092 means that, holding *exper* and *tenure* fixed, another year of education is predicted to increase log(wage) by .092, i.e., 9.2% increase in wage.
- ullet Alternatively, we can take two people, A and B, with the same exper and tenure. Suppose person B has one more year of schooling than person A. Then we predict B to have a wage that is 9.2% higher.

What Does it Mean to "Hold Other Factors Fixed"?

• The power of multiple regression analysis is that it provides the *ceteris paribus* interpretation, even though the data have **not** been collected in a *ceteris paribus* fashion.

$$\log(wage) = \beta_0 + \beta_1 educ + \beta_2 exper + \beta_1 tenure + u$$

- Using the multiple regression model for wage as an example, it may seem that we actually went out and sampled people with the same *exper* and *tenure*.
- It's not the case. It's a random sample.

Efficiency of OLS: The Gauss-Markov Theorem (1) The sample average of the residuals is zero, i.e., $\sum_{i=1}^n \hat{u}_i = 0$. This implies $\bar{y} = \bar{\hat{y}}$.

- (2) Each explanatory variable is uncorrelated with the residuals in the sample. This follows from the first order conditions. It implies that \hat{y}_i and \hat{u}_i are also uncorrelated.
- (3) The sample averages always fall on the OLS regression line:

$$\bar{y} = \hat{\beta}_0 + \hat{\beta}_1 \bar{x}_1 + \hat{\beta}_2 \bar{x}_2 + \dots + \hat{\beta}_k \bar{x}_k$$

That is, if we plug in the sample average for each explanatory variable, the predicted value is the sample average of the y_i .

• As with simple regression, it can be shown that

$$SST=SSE+SSR$$

where SST, SSE, and SSR are the total, explained, and residual sum of squares.

- Recall, $0 \le R^2 \le 1$
- Using the same set of data and the same dependent variable, the *R*-squared can never fall when another independent variable is added to the regression.

 And, it almost always goes up, at least a little.
- ullet This means that, if we focus on R^2 , we might include silly variables among the x_j .
- ullet Adding another x cannot make SSR increase. The SSR falls unless the coefficient on the new variable is identically zero.

Efficiency of OLS: The Gauss-Markov Be careful with functional forms! Suppose we start with a constant elasticity model of family consumption:

$$\log(cons) = \beta_0 + \beta_1 \log(inc) + u$$

• How might we allow the elasticity to be nonconstant, but include the above as a special case? The following does *not* work:

$$\log(cons) = \beta_0 + \beta_1 \log(inc) + \beta_2 \log(inc^2) + u$$

because $\log(inc^2) = 2\log(inc)$, that is, $x_2 = 2x_1$, where $x_1 = \log(inc)$.

Key Point

Assumption MLR.3 does *not* say the explanatory variables have to be uncorrelated in the population or sample.

Nor does it say they cannot be "highly" correlated.

MLR.3 rules out *perfect correlation* in the sample, that is, correlations of ± 1 .

- Multiple regression would be useless if we had to insist x_1 , ..., x_k were uncorrelated in the sample (or population)!
- ullet If the x_j were all pairwise uncorrelated, we could just use a bunch of simple regressions.

Efficiency of OLS: The Gauss-Markov

Theorem: Unbiasedness of OLS

Under Assumptions MLR.1 through MLR.4,

$$E(\hat{\beta}_j) = \beta_j$$
, $j = 0, 1, 2, ..., k$

for any values of the population parameters β_j . In other words, the OLS estimators are unbiased estimators of the population parameters.

Efficiency of DLS: The Gauss-Markov Theorem • So far, we have assumed

MLR.1: $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k + u$

MLR.2: random sampling from the population

MLR.3: no perfect collinearity in the sample

MLR.4: $E(u|x_1, x_2, ..., x_k) = 0$

- Under MLR.3 we can compute the OLS estimates in our sample.
- The other assumptions then ensure that OLS is unbiased (conditional on the outcomes of the explanatory variables).

- Now, our goal is to find $Var(\hat{\beta}_j)$.
- In order to do that we need to add another assumption: homoskedasticity (constant variance).
- Why should we add another assumption?
 - Imposing this assumption, the OLS estimator has an important feature/property: **efficiency**.
 - We can obtain simple formulas with it too.

Assumption MLR.5 (Homoskedasticity)

The variance of the error, u, does not change with any of $x_1, x_2, ..., x_k$:

$$Var(u|x_1, x_2, ..., x_k) = Var(u) = \sigma^2$$

ullet What it is saying is that the variance of the unobservable, u, conditional on $x_1, x_2, ..., x_k$ is constant.

- The homoskedasticity assumption is common in cross-section analysis. However there are many problems where it does not hold.
- For time series **hardly** (!) you can make this assumption.
- When $Var(u|x_1,x_2,...,x_k)$ depends on x_j , the error term exhibits **heteroskedasticity** (nonconstant variance)
- Since $Var(u|x_1,x_2,...,x_k) = Var(y|x_1,x_2,...,x_k)$, we have **heteroskedasticity** when $Var(y|x_1,x_2,...,x_k)$ is a function of x.

Multicollinearity: R_i^2 close to one. (problem of ...)

Perfect Collinearity: $R_i^2 = 1$ (not allowed under MLR.1 - MLR.4)

 Does multicollinearity (high correlation among two or more independent variables) violates any of the Gauss-Markov assumptions (including MLR.3.)?

Answer: No. Multicollinearity does not cause the OLS estimators to be biased. We still have $E(\hat{\beta}_i) = \beta_i$.
